Abstract

In this work we give a methodology for controller design and analysis which accounts for design criteria such as: (a) optimal system response to external disturbances, (b) robustness to modeling uncertainty, and (c) constraints on the controller order. The methodology is applied to a structural control benchmark problem sponsored by the ASCE Committee on Structural Control. The structural system considered consists of a scale model of a three-story building employing an active mass driver to suppress ground motion disturbances. The methodology proved effective for obtaining a satisfactory low-order controller for this class of problems.

1 Introduction

The goal of this paper is to report on a methodology for controller design and analysis which accounts for design criteria such as (a) optimal system response to external disturbances, (b) robustness to modeling uncertainty, and (c) constraints on the controller order. The

methodology does not include all of these objectives in the design stage; instead, a subset of objectives is optimized to produce a family of controllers that is screened later using the remaining criteria. The outcome of this screening process is the final controller.

We have used this methodology to design controllers for the structural control benchmark problems [1]. To keep this paper to a manageable size, we present the results for the first benchmark problem only. Briefly, the solution we obtained for this problem has the following features:

- 8th-order stable controller.
- The structural responses (interstory drifts and floor accelerations), to random ground disturbances, are reduced by 63%; these responses are optimal.
- The structural responses, to the Hachinohe and El Centro earthquakes, are reduced by 39%.
- The hard constraints on commanded actuator voltage, displacement and acceleration of the active mass driver, are all met.
- The compensated loop gain is less than $-20\text{db}$ at all frequencies outside the range 5Hz to 31Hz; thus, the control bandwidth contains the first three structural modes only, and it ensures robustness of stability and performance to unmodeled dynamics.
- Robust stability is guaranteed for simultaneous variations in the first three structural modes (the controlled modes) of at least $21\%$ in natural frequencies and $53\%$ in damping ratios.

The paper contains five more sections and three appendices. In section 2, we give a brief description of the design model. Section 3 summarizes the evaluation criteria, and controller implementation constraints, of the benchmark problem. The methodology for controller design and analysis is in section 4. A key contribution of this section, which should prove useful to other groups working in the benchmark problem, is the optimal tradeoff surface between the system response to random disturbances and the cost of actuation. This surface can be used to make quantitative comparisons among the controllers obtained for the first benchmark problem. Controller order reduction and robustness analysis tests are part of the methodology and they are included in section 4 also. Section 5 contains the results of the time-domain simulations performed with the SIMULINK model introduced in [1]. The appendices summarize the methods and tools required to implement our methodology.
2 Design model

The model used for controller design and analysis is the evaluation model described in [1]. This model has 28 states and it is given by the following equations

\[
\begin{align*}
\dot{x} &= Ax + E\ddot{x}_g + Bu, \\
y &= Cy + F_y\ddot{x}_g + D_y u,
\end{align*}
\]

where \(x\) is the state vector, \(\ddot{x}_g\) is the ground acceleration, \(u\) is a scalar control input, and \(y\) is the measurement vector available to the controller. The measurement vector \(y\) is partitioned into \(y^T = [y_1^T \ y_2]\), where

\[
y_1 = \begin{bmatrix} x_m \\ \ddot{x}_{a1} \\ \ddot{x}_{a2} \\ x_{am} \end{bmatrix} \quad \text{and} \quad y_2 = \ddot{x}_g.
\]

The units of the control input \(u\) and the measurement \(y\) are volts; thus, the input-output map from \(u\) to \(y\) is nondimensional.

No attempt is made to reduce the order of the model for design purposes. This is because the number of states is within the range that can be handled by the design methods used in this paper.

The controllers are designed using continuous-time methods without taking into account time/amplitude quantizations; these discretizations are incorporated later to obtain the implementable control laws. The notation used for the ideal control law is

\[
u = C_1 y_1 + C_2 y_2
\]

where \(C_1\) and \(C_2\) denote continuous-time linear time-invariant dynamical systems; \(C_1\) is a feedback controller while \(C_2\) is a feedforward controller. The notation used for the overall controller is

\[
C = \begin{bmatrix} C_1 & C_2 \end{bmatrix}.
\]

3 Evaluation criteria and implementation constraints

The evaluation criteria and implementation constraints are defined in [1] and repeated here for completeness.
3.1 Stochastic evaluation criteria

In this case, the ground acceleration $\ddot{x}_g$ is a stationary stochastic process with power spectral density

$$S_{\ddot{x}_g}(\omega, \omega_g, \zeta_g) = S_0(\omega_g, \zeta_g) \frac{4\zeta_g^2\omega_g^2 + \omega^4}{(\omega - \omega_g^2 + 4\zeta_g^2\omega_g^2\omega^2} \quad (5)$$

where the natural frequency $\omega_g$ and the damping ratio $\zeta_g$ lie in prescribed intervals. The scaling factor $S_0$ keeps constant the rms value of the ground acceleration irrespective of changes in $\omega_g$ and $\zeta_g$.

In addition to this ground disturbance, the entire measurement vector $y$ is corrupted by the measurement noise $v$. Each component of the measurement noise is modeled as a stationary white noise process.

When both the random ground disturbance and the measurement noise are applied to the structure, the effectiveness of the controller is to be measured by the following criteria\(^1\):

$$J_1 = \max \left\{ \frac{\sigma_{d1}}{\sigma_{x_{30}}}, \frac{\sigma_{d2}}{\sigma_{x_{30}}}, \frac{\sigma_{d3}}{\sigma_{x_{30}}} \right\} \quad (6a)$$

$$J_2 = \max \left\{ \frac{\sigma_{\ddot{x}_{a1}}}{\sigma_{\ddot{x}_{a20}}}, \frac{\sigma_{\ddot{x}_{a2}}}{\sigma_{\ddot{x}_{a20}}}, \frac{\sigma_{\ddot{x}_{a3}}}{\sigma_{\ddot{x}_{a20}}} \right\} \quad (6b)$$

$$J_3 = \max \left\{ \frac{\sigma_{x_m}}{\sigma_{x_{30}}} \right\} \quad (6c)$$

$$J_4 = \max \left\{ \frac{\sigma_{\dot{x}_m}}{\sigma_{\dot{x}_{30}}} \right\} \quad (6d)$$

$$J_5 = \max \left\{ \frac{\sigma_{\ddot{x}_{am}}}{\sigma_{\ddot{x}_{a20}}} \right\} \quad (6e)$$

where the interstory drifts $d_i$ are the relative lateral displacements between floors ($d_1 = x_1$, $d_2 = x_2 - x_1$, $d_3 = x_3 - x_2$), $\dot{x}_i$ is the lateral velocity of floor $i$, and $\ddot{x}_a$ represents the absolute lateral acceleration of floor $i$. The signals $x_m$, $\dot{x}_m$ and $\ddot{x}_{am}$ are the displacement (relative to the 3rd floor), velocity and absolute acceleration of the active mass driver. Finally, the normalization constants $\sigma_{x_{30}}$, $\sigma_{\dot{x}_{30}}$, and $\sigma_{\ddot{x}_{a30}}$ are, respectively, the worst case rms values of the 3rd floor position, velocity and absolute acceleration, over all allowed values of $\omega_g$ and $\zeta_g$, when the loop is open.

In addition, the following hard constraints must be met

$$\sigma_u \leq 1 \text{ v, } \sigma_{\ddot{x}_{am}} \leq 2 \text{ g, } \sigma_{x_m} \leq 3 \text{ cm.} \quad (7)$$

\(^1\)We use the symbol $\sigma_x$ to denote the rms value of a stochastic signal $x$. 

4
The criteria (6) and the rms values defining the constraints (7) depend on the parameters \( \omega_g \) and \( \zeta_g \) of the disturbance model (5). When evaluating the criteria, and constraints, for a given controller, these quantities need to be maximized over \( \omega_g \) and \( \zeta_g \) to determine the worst possible values. This is to be done using the following ranges

\[
3.18 \text{ Hz} \leq \omega_g \leq 19.1 \text{ Hz}, \quad 0.3 \leq \zeta_g \leq 0.7.
\] (8)

3.2 Deterministic evaluation criteria

In this case, the ground acceleration is one of two historical earthquake records: 1940 El Centro NS and 1968 Hachinohe NS. The controller is evaluated according to the following criteria:

\[
J_6 = \max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t \left\{ \frac{|d_1(t)|}{x_{30}}, \frac{|d_2(t)|}{x_{30}}, \frac{|d_3(t)|}{x_{30}} \right\}
\] (9a)

\[
J_7 = \max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t \left\{ \frac{|\ddot{x}_{30}(t)|}{x_{30}}, \frac{|\ddot{x}_{a30}(t)|}{x_{30}}, \frac{|\ddot{x}_{a30}(t)|}{x_{30}} \right\}
\] (9b)

\[
J_8 = \max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t \frac{|x_{30}(t)|}{x_{30}}
\] (9c)

\[
J_9 = \max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t \frac{|\dot{x}_{30}(t)|}{x_{30}}
\] (9d)

\[
J_{10} = \max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t \frac{|\dddot{x}_{a30}(t)|}{x_{30}}
\] (9e)

where \( x_{30}, \dot{x}_{30} \) and \( \ddot{x}_{a30} \) are the largest peak values, taken over both earthquake records, of the 3rd floor position, velocity and absolute acceleration, respectively, when no controller is present.

In addition, the following hard constraints must be met

\[
\max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t |u(t)| \leq 3 \text{ v}
\] (10a)

\[
\max_{\text{El Centro}} \max_{\text{Hachinohe}} \max_t |\dddot{x}_{a30}(t)| \leq 6 \text{ g}
\] (10b)
\[ \max_i \max_t |x_m(t)| \leq 9 \text{ cm.} \tag{10c} \]

3.3 Implementation constraints

The controller for the structural control benchmark problem must be delivered in discrete time \([1]\). The discrete-time controller is to operate at 1kHz sampling rate, and it must satisfy the following implementation constraints: (a) open loop stable, and (b) order no higher that 12 states.

4 Optimization-based design methodology

In this section we formulate the controller design problem as a multiobjective optimization problem. The precise steps used for controller design are shown below.

1. Select the \emph{nominal} parameters \(\omega_d\) and \(\zeta_d\) for the random ground disturbance model in (5), within the ranges shown in (8), which will be used for controller design.

2. Using the disturbance model selected in step 1, compute the \emph{optimal tradeoff surface} between the stochastic actuation costs and stochastic structural response, subject to the hard constraints (7). This step produces a \emph{set} of controllers that optimizes the stochastic structural response and the stochastic actuation costs.

3. Reduce the order of the optimal controllers obtained in step 2 to generate a set of low order controllers that meet the stochastic hard constraints, and whose structural responses and actuation costs are as close as possible to the optimal tradeoff surface computed in step 2.

4. Compute the subset of low order controllers that meet the deterministic hard constraints (10).

5. Analyze the robustness to variations in the disturbance model (5), variations in structural parameters, and unmodeled dynamics, of the set of low order controllers computed in step 4 and select a final candidate for implementation.
4.1 Achievable performance with stochastic disturbances

Given the parameters, $\omega_g$ and $\zeta_g$, of the disturbance model (5), and a controller, the structural response of the system can be measured by the single performance measure

$$J_{\text{per}} = \max\{r_1 J_1, J_2\}$$ (11)

where the positive number $r_1$ provides the relative weight between the interstory drifts ($J_1$) and floor absolute accelerations ($J_2$). The actuation cost can be measured by

$$J_{\text{act}} = \max\{r_3 J_3, r_4 J_4, J_5\}$$ (12)

where $r_3$ and $r_4$ are positive numbers providing relative weighting among the actuator displacement ($J_3$), actuator velocity ($J_4$) and actuator acceleration ($J_5$).

Performance improvement, i.e. reduction of $J_{\text{per}}$, can only be obtained at the expense of an increase in $J_{\text{act}}$. The optimal tradeoff between $J_{\text{per}}$ and $J_{\text{act}}$ may be computed by solving the following constrained optimization problem:

$$J_{\text{act}}^{\text{opt}}(q) = \min J_{\text{act}}$$

subject to

$$J_{\text{per}} \leq q J_{\text{per}}^{\text{ol}}$$

$$\sigma_u \leq 1 \text{ v}, \sigma_{x_m} \leq 3 \text{ cm}, \sigma_{x_{am}} \leq 2 \text{ g}$$

where $J_{\text{per}}^{\text{ol}}$ is the performance cost for the open loop system, the parameter $q$ satisfies the inequality $0 \leq q \leq 1$, and the minimization is performed over all the controllers $C$ (see equation (4)) that stabilize the system.

A solution to problem (13) gives a controller that satisfies the stochastic hard constraints (7), and achieves a performance cost $J_{\text{per}}$ no greater than $q J_{\text{per}}^{\text{ol}}$ with the least possible actuation effort. By sweeping $q$ between zero and one, the tradeoff curve between $J_{\text{per}}$ and $J_{\text{act}}$ may be generated. This gives a family of controllers which are Pareto optimal for the costs $J_{\text{per}}$ and $J_{\text{act}}$ when the hard constraints are met. This family may be screened for other performance measures and/or robustness properties to select the final controller candidates. Details for solving (13) are given in appendix A.

The parameters used for solving problem (13) are shown in Table 1. The relative weights $r_1$, $r_3$ and $r_4$ are taken to be one because no information justifying the preference of one cost over another was provided. We take the nominal values of $\omega_g$ and $\zeta_g$ to be the worst-case for the uncontrolled (open loop) structure [1]. In this problem this is a very logical choice. Partly, this is because to improve the structural response, with the least actuation effort, the controller should increase the damping of the modes that define performance without
changing their natural frequencies. Later, it will be shown that our designs do satisfy this property.

Figure 1 gives the tradeoff curve between $J_{\text{per}}$ and $J_{\text{act}}$. This figure is obtained by solving (13), with $0.19 \leq q \leq 0.63$, and plotting $J_{\text{per}}(q)$ against its corresponding value of $J_{\text{act}}^{\text{opt}}(q)$. This result states that there exists no stabilizing controller meeting the stochastic hard constraints with both $J_{\text{act}}$ and $J_{\text{per}}$ below the optimal tradeoff curve. The individual costs $J_1$ to $J_5$ and the rms values of $u$, $x_m$ and $\ddot{x}_m$ are plotted against $q$ in Figure 2. Frames (3,2), (4,1), and (4,2), show that the hard constraints (7) and (10) are met.

The tradeoff curve in Figure 1 should prove useful to other groups working with the benchmark problem for this curve can be used to make quantitative comparisons among the controllers obtained for the first benchmark problem.

### 4.2 Controller reduction

The controllers lying on the optimal tradeoff plot of Figure 1 have order 30. These controllers were reduced applying the weighted balance and truncation method on a coprime factorization of the controllers. The weight was selected to guarantee closed loop stability with the reduced-order controllers. As left and right coprime factor reduction can give different results, both methods were applied. Details of the methods are given in appendix B. Using this method a set of 10th-order controllers was obtained.

The tradeoff, between $J_{\text{act}}$ and $J_{\text{per}}$, achieved by the reduced-order controllers is shown Figure 3. This set of 10th-order controllers is practically optimal. The individual costs $J_1$ to $J_6$, and rms values of the signals that must satisfy hard constraints, are plotted in Figure 4 together with the optimal ones. There is no difference between the optimal values and the values attained by the reduced-order controllers.

### 4.3 Response to deterministic disturbances

The time domain specifications, namely costs $J_6$ to $J_{10}$ and hard constraints in the peak values of $u$, $x_m$, and $\ddot{x}_m$, for two earthquake records, were not included in the optimization problem
Solutions to (13) are not guaranteed to satisfy the time domain hard constraints (10), nor the costs $J_6$ to $J_{10}$ are guaranteed to be optimal in any sense. As a result, further analysis is needed to obtain a set of controllers that meet all specifications.

Figure 5 shows the results of the time domain analysis for the reduced-order controllers. The subset of reduced-order controllers that meets all constraints is obtained when $q \geq 0.34$, see frame (4,2) in Figure 5. Once again, the optimal controllers and the reduced-order controllers show the same behavior in response to the deterministic disturbances.

### 4.4 Admissible controller

Based on the analysis performed so far, the 10th-order controller with $q = 0.34$ gives the best performance for both random and deterministic disturbances. In addition this controller meets all the hard constraints of the problem. A closer examination of the individual SISO transfer functions of this 10th-order controller showed near zero-pole cancelations in each transfer function which were not removed by the model reduction scheme. After removing these near zero-pole cancelations we obtained an 8th-order controller with almost identical performance. We shall refer to this 8th-order controller as the admissible controller.

The next three subsections contain the results of several robustness tests that demonstrate that the admissible controller is a good candidate for implementation.

### 4.5 Uncertainty in the random disturbance model

Figures 6 and 7 show, respectively, the values of $J_{act}$ and $J_{per}$ for the 8th-order admissible controller, as the parameters $\omega_g$ and $\zeta_g$ of the disturbance model (5) vary in the ranges given in (8). The plots clearly show that the worst-case closed loop costs are achieved at the open loop worst-case values $\omega_{g0} = 5.94$ Hz, $\zeta_{g0} = 0.3$.

The fact that the worst-case closed loop parameters $\omega_g$ and $\zeta_g$ are the worst-case parameters for the uncontrolled structure is not exclusive to $q = 0.34$. Variations in the stochastic evaluation criteria with $\omega_g$ and $\zeta_g$ are shown in Figure 8 for the 10th-order controllers with $q = 0.34, 0.44, 0.54, 0.63$. From Figure 8 it follows that all stochastic evaluation criteria reach their maximum value at the open loop worst-case parameters.

### 4.6 Feedback properties and robustness to unmodeled dynamics

This section contains several frequency domain tests corresponding to the 8th-order admissible controller. We make use of the following notation. The open loop transfer matrix from
$u$ to $y_i$ in equations (1) and (2), is denoted by $P_{y_1 u}(s)$. The transfer matrix of the feedback controller $C_i$ in equation (3) is denoted by $K_i(s)$.

Figure 9 shows the loop gain, with the loop broken at the plant input $u$; i.e., the magnitude of the frequency response $K_i(j\omega)P_{y_1 u}(j\omega)$. The loop gain is less than 0.1 (−20db) outside the frequency interval $[5, 31]$ Hz. The roll-offs at high and low frequencies are adequate for the evaluation model is accurate up to 100 Hz [1]. Figure 10 shows the Nyquist plot of $-K_i(j\omega)P_{y_1 u}(j\omega)$. The gain margin is 5.4 at 20.9 Hz. The phase margin is 57.1 deg at 18.1 Hz. These are good margins.

Figure 11 shows the variation of the closed loop poles with the controller gain; i.e., the zeros of the characteristic equation

$$1 - \text{gain} \ K_1(s)P_{y_1 u}(s) = 0$$

when the gain is changed from 0 to 5.4 (the gain margin of the system). The three poles close to the imaginary axis are structural modes, the remaining 4 poles are all the controller modes.

From Figures 9 and 11, it follows that the feedback component of the controller improves the structural response by increasing the damping of the first three structural modes without changing their (damped) natural frequencies.

Figure 12 shows the largest singular value ($\sigma_{\text{max}}$) of the complementary sensitivities at plant input and output. These transfer functions are given by

$$T_i(s) = (1 - K_1(s)P_{y_1 u}(s))^{-1}K_1(s)P_{y_1 u}(s) \text{ (at plant input)}$$

$$T_o(s) = (I - P_{y_1 u}(s)K_1(s))^{-1}P_{y_1 u}(s)K_1(s) \text{ (at plant output)}$$

From the plot of $\sigma_{\text{max}}(T_i(j\omega))$ we conclude that noise in the control input $u$ is attenuated at all frequencies. From the plot of $\sigma_{\text{max}}(T_o(j\omega))$ we conclude that noise in the feedback sensors, the linear variable differential transformer and the accelerometers measuring actuator and floor accelerations, is attenuated at all frequencies except for a tiny interval around 18Hz.

The complementary sensitivities shown in Figure 12 also give the stability margin to multiplicative (or relative) uncertainty at plant input and plant output [2, 3]. For example, suppose the true transfer matrix of the structure, from the control input to the feedback sensors, is given by

$$P_{y_1 u,\text{true}}(s) = P_{y_1 u}(s)(1 + e_i(s))$$

where $e_i(s)$ denotes relative modeling error at plant input; e.g., due to unmodeled actuator dynamics. If $e_i(s)$ is stable then the closed loop system will remain stable as long as

$$|e_i(j\omega)| < \frac{1}{\sigma_{\text{max}}(T_i(j\omega))}$$

10
for all frequencies. Hence, from Figure 12 it follows that \( \epsilon_i \) could be as large as 100% without de-stabilizing the closed loop; in fact, at frequencies other than the first three structural modes the stability margin is well above 100%. Similarly, the plot of \( \sigma_{\text{max}}(T_o(j\omega)) \) shows that multiplicative perturbations at plant output; i.e., perturbations of the form

\[
P_{y_1 u,\text{true}}(s) = (I + E_o(s))P_{y_1 u}(s),
\]

which account for unmodeled sensor dynamics, could be as large as 100% without de-stabilizing the closed loop, except for a tiny interval around 18Hz in which \( \sigma_{\text{max}}(E_o(j\omega)) \) should not exceed 66%.

### 4.7 Parametric uncertainty

A \( \mu \) test [2, 4] was performed to determine stability when the natural frequencies and damping ratios of the first three natural modes are perturbed simultaneously. Recall from the previous subsection that these modes determine the performance of the controlled structure. The nominal frequencies, and damping ratios, of these modes are: \( \omega_1 = 5.81 \) Hz \( \zeta_1 = 0.33\% \), \( \omega_2 = 17.68 \) Hz \( \zeta_2 = 0.23\% \), \( \omega_3 = 28.53 \) Hz \( \zeta_3 = 0.30\% \).

The closed loop system is guaranteed to remain stable when the structural parameters are perturbed by the following amounts: 21% in natural frequencies (pole magnitude) and 53% in the damping ratios. The upper bound for \( \mu \) for this simultaneous parameter variation is shown in Figure 13. The interconnection structure required to perform this analysis is given in appendix C.

### 5 Controller validation

The 8th-order admissible controller was discretized using the bilinear Tustin transform with a 1kHz sampling rate. Since the magnitudes of the controller zeros and poles are below 31Hz, the discretization showed no problems with good match between the discrete and continuous time frequency responses. The continuous-time controller is open loop stable (see the controller poles in Figure 11); thus, since we use the bilinear transform, so is the discretized version.

The final linear discrete-time controller was simulated in the time-domain using the non-linear SIMULINK program given in [1]. This program contains the linear evaluation model, the A/D and D/A converters with 12-bit precision and a span of \( \pm 3v \), the random and deterministic ground disturbances, and the sensor noises with 0.01v rms value.
The effectiveness of the controller can be seen by comparing the open and closed-loop time histories. Figure 14 shows the time histories for the 3rd floor acceleration $\ddot{x}_{33}$ and the 1st floor interstory drift $d_1$, when the system is excited with El Centro earthquake record. Figure 15 shows how these variables respond to the Hachinohe earthquake. We only show the 3rd floor acceleration, and the 1st interstory drift, because these are the largest acceleration and drift.

From the simulations, we obtained the actual values of the evaluation criteria defined in section 3, with the 8th-order admissible controller. The analytical values of the evaluation criteria correspond to the (linear) continuous-time closed loop. The results for the case of random disturbances, are shown in Table 2, and the results for the case of deterministic disturbances are shown in Table 3.

The following conclusion is immediate from these tables: The controller reduces the random interstory drift, and floor acceleration, responses by 63%, or more. The controller reduces the deterministic interstory drift, and floor acceleration, responses by 39%. All hard constraints are met.

---

2The actual values of the stochastic evaluation criteria were computed using the worst case parameters $\omega_g$ and $\zeta_g$ in (5) for the linear, continuous-time closed loop, obtained as shown in section 4.5. The reason for using these worst case parameters is that the computation of the worst case parameters for the linear system is much less expensive than the computation of those for the nonlinear system. This choice is justified in that the nonlinear effects considered in the simulations are mild, and then no sensible differences are expected between the worst case parameters for both systems.

Table 3: Evaluation criteria with 8th-order admissible controller—Hachinohe and El Centro earthquakes.
A Solution to optimization problem

The optimization problem (13) is solved using the method presented in [5].

Step 1

Obtain a realization for the linear time invariant system that includes the structural model (1), the stochastic ground disturbance model (5), and the white measurement noise, of the form

\begin{align}
\dot{\eta} &= A\eta + B_1 \begin{bmatrix} w_g \\ v_n \end{bmatrix} + B_2 u \\
&= C_1 \eta + D_{11} \begin{bmatrix} w_g \\ v_n \end{bmatrix} + D_{12} u \\
y &= C_2 \eta + D_{21} \begin{bmatrix} w_g \\ v_n \end{bmatrix} + D_{22} u.
\end{align}

The signal \( w_g \) is a normalized (unit spectral density) white noise process representing the input to the disturbance model, \( v_n \) is the normalized sensor noise process uncorrelated with \( w_g \), \( u \) is the control signal (in volts), and \( y \) is the six-component measurement vector (in volts). The vector of controlled responses \( z \) has twelve components and it is defined by

\begin{align}
z_1 &= r_3 \sigma_{\text{per}} \\
z_2 &= r_4 \sigma_{\text{per}} \\
z_3 &= \frac{x_m}{\sigma_{\text{per}}} \\
z_4 &= \frac{x_m}{2} \\
z_5 &= \frac{x_m}{3 \ \text{cm}} \\
z_6 &= \frac{x_m}{\sigma_{\text{per}}} \sigma_{\text{per}}.
\end{align}

where \( q \) and \( J_{\text{per}}^{\text{ex}} \) are as in (13).

Define the exogenous input \( w = [w_g^T, v_n^T]^T \). Pick a stabilizing controller \( C \) (see equation (4)) and let \( T_{z_i w} \) denote the closed loop transfer matrix from \( w \) to \( z_i \), for \( i = 1, \ldots, 12 \). Standard results [6] show that the optimization problem (13) is equivalent to the following problem:

\begin{align}
\min_C \gamma \text{ subject to } & \\
\|T_{z_i w}\|_2 &< \gamma \quad i = 1, \ldots, 3 \\
\|T_{z_i w}\|_2 &< 1 \quad i = 4, \ldots, 12
\end{align}
where the minimization is performed over all stabilizing controllers $C$ and the symbol $\| \cdot \|_2$ denotes the $\mathcal{H}_2$ norm of a transfer matrix defined by

$$\|T\|_2 = \sqrt{\frac{1}{2\pi} \text{trace} \int_{-\infty}^{\infty} T(j\omega)T^*(j\omega) d\omega}.$$  

The formulas presented in the following steps are valid for $D_{11} = 0$, a condition that holds for (20).

**Step 2**

Obtain the real, symmetric, stabilizing solution $\tilde{Y}$ to the algebraic Riccati equation

$$AY + YAT + B_1B_1^T - (YC_2^T + B_1D_{21}^T) \left(D_{21} D_{21}^T\right)^{-1} (C_2Y + D_{21}B_1^T) = 0.$$  

**Step 3**

Given $\tilde{Y}$ and a small number $\beta$ [5], find any real symmetric $Q_p$ and any real $W_p$ satisfying the linear equation

$$AQ_p + Q_pAT + B_2W_p + W_pB_2^T + (\tilde{Y}C_2^T + B_1D_{21}^T) \left(D_{21} D_{21}^T\right)^{-1} (C_2\tilde{Y} + D_{21}B_1^T) + \beta I = 0,$$

which has solution because $(A, B_2)$ is stabilizable.

**Step 4**

Find a basis $\{(Q_j, W_j)\}_{j=1,\cdots,r}$ for the linear subspace

$$\left\{(Q, W) : Q = QT, AQ + QA^T + B_2W + W^TB_2^T = 0\right\}.$$  

**Step 5**

Solve the following convex optimization problem on the scalar variables $\gamma^2, a_1, \cdots, a_r$:

$$\min \gamma^2 \quad \text{subject to} \quad (22)$$

\[
\begin{bmatrix}
\gamma^2 - C_{1i}^T \tilde{Y} C_{1i} & C_{1i}Q + D_{1i}W \\
(C_{1i}Q + D_{1i}W)^T & Q
\end{bmatrix} \geq 0, \quad i = 1, \cdots, 3
\]

\[
\begin{bmatrix}
1 - C_{1i}^T \tilde{Y} C_{1i} & C_{1i}Q + D_{1i}W \\
(C_{1i}Q + D_{1i}W)^T & Q
\end{bmatrix} \geq 0, \quad i = 4, \cdots, 12
\]

$$Q = Q_p + \sum_{j=1}^{r} a_j Q_j$$

$$W = W_p + \sum_{j=1}^{r} a_j W_j$$
where $C_{1i}; (D_{1i})$ is the $i^{th}$ row of $C_1 (D_1)$. Problem (22) can be efficiently solved using standard software tools [7].

Step 6

Denote an optimal solution to (22) by $\{ r^{\text{opt}}, a^{\text{opt}}_1 , \ldots , a^{\text{opt}}_r \}$, and define the optimal matrices $Q^{\text{opt}}$ and $W^{\text{opt}}$ as follows:

$$Q^{\text{opt}} = \sum_{j=1}^{r} a^{\text{opt}}_j Q_j$$

$$W^{\text{opt}} = \sum_{j=1}^{r} a^{\text{opt}}_j W_j.$$

A stabilizing controller solving (13) has the following realization:

$$\begin{bmatrix} A_k & B_k \\ C_k & D_k \end{bmatrix} = \begin{bmatrix} A + HC_2 + B_2 F + HD_2 F & H \\ F & 0 \end{bmatrix}^{-1}$$

where $F = W^{\text{opt}} (Q^{\text{opt}})^{-1}$ and $H = -(\tilde{V} C_2^T + B_2 D_{21}^T) \left( D_{21} D_{21}^T \right)^{-1}$.

B Controller reduction

This appendix describes the procedure used to obtain reduced-order controllers. The reduction was performed applying the weighted balance and truncation method on a controller coprime factorization, where the weight is chosen to preserve closed loop stability. The method is presented in [8, 2]. The two procedures described below correspond to the truncation of left and right controller factorizations.

Stability Weighted Left Coprime Factorization

Step 1

Find a left coprime factorization $(\tilde{V}(s), \tilde{U}(s))$ [2, 3] of the controller transfer matrix $K(s)$; e.g., compute stable matrices $(\tilde{V}(s), \tilde{U}(s))$ satisfying $K(s) = \tilde{V}^{-1}(s) \tilde{U}(s)$.

Step 2

Obtain a minimal realization for the weight $W(s)$ defined by

$$W(s) = \begin{bmatrix} -P_{yu}(s) \\ I \end{bmatrix} (I - K(s) P_{yu}(s))^{-1} \tilde{V}^{-1}(s),$$
where \( P_{yu}(s) \) is the transfer matrix from control signal \( u \) to the measurement vector \( y \), which is stabilized by the controller \( K(s) \).

**Step 3**

Apply the weighted balance and truncation method, given in [8, 2, 9], to the system

\[
\begin{bmatrix}
\hat{U}(s) & \hat{V}(s)
\end{bmatrix} W(s)
\]

to obtain the reduced-order coprime factors

\[
\begin{bmatrix}
\hat{U}(s) & \hat{V}(s)
\end{bmatrix}.
\]

The reduced-order controller \( \hat{K}(s) \) is given by

\[
\hat{K}(s) = \hat{V}^{-1}(s)\hat{U}(s),
\]

and it is guaranteed to stabilize the system \( P_{yu}(s) \) if

\[
\left\| \begin{bmatrix}
\hat{U}(s) - \hat{U}(s) & \hat{V}(s) - \hat{V}(s)
\end{bmatrix} W(s) \right\|_{\infty} < 1.
\]

**Stability Weighted Right Coprime Factorization**

**Step 1**

Find a right coprime factorization \( (V(s), U(s)) \) of the controller transfer matrix \( K(s) \); e.g., compute stable matrices \( (V(s), U(s)) \) satisfying \( K(s) = U(s)V^{-1}(s) \).

**Step 2**

Obtain a minimal realization for the weight \( W(s) \) defined by

\[
W(s) = V^{-1}(s) \left( I - P_{yu}(s)K(s) \right)^{-1} \left[ \begin{array}{cc}
-P_{yu}(s) & I
\end{array} \right],
\]

where \( P_{yu} \) is the transfer matrix from control signal \( u \) to measurement vector \( y \), which is stabilized by the controller \( K(s) \).

**Step 3**

Apply the weighted balance and truncation method, given in [8, 2, 9], to the system

\[
W(s) \begin{bmatrix}
U(s) \\
V(s)
\end{bmatrix}
\]
to obtain the reduced-order coprime factors

\[
\begin{bmatrix}
\hat{U}(s) \\
\hat{V}(s)
\end{bmatrix}.
\]

The reduced-order controller \( \hat{K}(s) \) is given by

\[
\hat{K}(s) = \hat{U}(s)\hat{V}^{-1}(s),
\]

and is guaranteed to stabilize the system \( P_{yu}(s) \) if

\[
\left\| W(s) \begin{bmatrix}
U(s) - \hat{U}(s) \\
V(s) - \hat{V}(s)
\end{bmatrix} \right\|_{\infty} < 1.
\]

### C Interconnection structure for \( \mu \) test

The \( \mu \)-test in section 4.7 requires a description of the parametric uncertainty, in the first three structural modes, for the transfer matrix \( P_{yu} \) from \( u \) to \( y \) defined in (1) and (2).

**Step 1**

Use the evaluation model to compute the following expansion for the nominal \( P_{yu} \)

\[
P_{yu}(s) = \sum_{i=1}^{3} \frac{C_{i1} s + C_{i2}}{s^2 + 2\zeta_0 \omega_0 s + \omega_0^2} + R(s)
\]

where the first three terms contain the dynamics of the first three structural modes, and \( R \) contains the remaining dynamics. In (23), \( C_{ij} \) is a column vector of dimension five, \( \omega_0 \) and \( \zeta_0 \) are the nominal frequency and damping ratio of mode \( i \).

**Step 2**

Model the perturbations in the natural frequencies and damping ratios, of the first three structural modes, using the equations

\[
P_{yu}^{per}(s) = \sum_{i=1}^{3} P^i(s) + R(s)
\]

\[
P^i(s) = \frac{C_{i1} s + C_{i2} (\omega_i/\omega_0)^2}{s^2 + 2\zeta_i \omega_i s + \omega_i^2}
\]

where \( \omega_i = \omega_0(1 + W_{\omega_i} \delta_{\omega_i}) \), \( \zeta_i = \zeta_0(1 + W_{\zeta_i} \delta_{\zeta_i}) \), \( \delta_{\omega_i} \) and \( \delta_{\zeta_i} \) denote real parametric variations with magnitude less than one, \( W_{\omega_i} > 0 \) and \( W_{\zeta_i} > 0 \) specify the size of the uncertainty and are defined by the user. Notice, from (24b), that the high and low frequency behavior of \( P^i(s) \) is independent of the perturbations in \( \omega_i \) and \( \zeta_i \).
Step 3

Isolate the uncertain parameters in (24b) by writing each uncertain component $P^i(s)$ as follows:

$$P^i(s) = G^i_{22}(s) + G^i_{21}(s) \Delta^i (I - G^i_{11} \Delta^i)^{-1} G^i_{12}(s)$$  \hspace{1cm} (25a)

$$\begin{bmatrix} G^i_{11} & G^i_{12} \\ G^i_{21} & G^i_{22} \end{bmatrix} = \begin{bmatrix} C^i_1 \\ C^i_2 \end{bmatrix} (sI - A^i)^{-1} \begin{bmatrix} B^i_1 & B^i_2 \end{bmatrix} + \begin{bmatrix} D^i_{11} & 0 \\ D^i_{21} & 0 \end{bmatrix}$$  \hspace{1cm} (25b)

$$\Delta^i = \begin{bmatrix} \delta_{\omega_i} & 0 & 0 \\ 0 & \delta_{\omega_i} & 0 \\ 0 & 0 & \delta_{\zeta_i} \end{bmatrix}$$  \hspace{1cm} (25c)

where

$$A^i = \begin{bmatrix} 0 & \omega_{\pi i} \\ -\omega_{\pi i} & -2\zeta_{\pi i}\omega_{\pi i} \end{bmatrix} \quad B^i_1 = \begin{bmatrix} W_{\omega_i} & 0 & 0 \\ -2\zeta_{\pi i} W_{\omega_i} & -W_{\omega_i} & -W_{\zeta_i} \end{bmatrix} \quad B^i_2 = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$$

$$C^i_1 = \begin{bmatrix} 0 & \omega_{\pi i} \\ \omega_{\pi i} & 0 \\ 0 & 2\zeta_{\pi i}\omega_{\pi i} \end{bmatrix} \quad D^i_{11} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 2\zeta_{\pi i} W_{\omega_i} & 0 & 0 \end{bmatrix} \quad D^i_{21} = \begin{bmatrix} 0 & \frac{W_{\omega_i}}{\omega_{\pi i}} C^i_1 \\ C^i_2 \end{bmatrix}.$$

It now follows from (24a) and (25a) that the perturbed transfer matrix $P_{y_1 u}^{\text{per}}(s)$ is the transfer matrix, from $u$ to $y_1$, in the block diagram shown in Figure 16, where the transfer matrix $G^i$ is given by

$$G^i = \begin{bmatrix} G^i_{11} & G^i_{12} \\ G^i_{21} & G^i_{22} \end{bmatrix}.$$

Thus, $P_{y_1 u}^{\text{per}}(s)$ is now in the format necessary for the $\mu$ test [4, 2].
